## ABSTRACT

Ag/Al<sub>2</sub>O<sub>3</sub> catalysts synthesized by the common impregnation technique with various Ag loadings were characterized by the NO<sub>x</sub>-Temperature-Programmed Desorption (TPD) method and their catalytic performances were evaluated in the selective catalytic reduction of NO<sub>x</sub> by propene (C<sub>3</sub>H<sub>6</sub>-SCR). It was found that the NO<sub>x</sub> uptake decreased linearly as the Ag surface density increased up to about 0.7 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub> and then leveled off. This behavior was attributed to the formation of a pseudo monolayer of Ag<sub>2</sub>O clusters, i.e. to the maximum loading of silver per unit surface area of Al<sub>2</sub>O<sub>3</sub> (0.7 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub>) for which highly dispersed Ag<sub>2</sub>O clusters are preserved on freshly calcined samples. It was also found that this optimum Ag surface density could be correlated to the catalytic performances in the C<sub>3</sub>H<sub>6</sub>-SCR of NO<sub>x</sub>. The concept of Ag surface density allowed rationalizing some of the earlier results on C<sub>3</sub>H<sub>6</sub>-SCR of NO<sub>x</sub>.

## 1. Introduction

To prevent global warming, which is partly attributable to the emissions of CO<sub>2</sub> from transportation vehicles, improved efficiency of the engines has been targeted to lower fuel consumption and hence CO<sub>2</sub> emissions. Lean burn engines, used in gasoline and diesel powered vehicles and operating in an excess of O<sub>2</sub>, are intrinsically more fuel-efficient than the gasoline engines developed earlier, which typically operated under stoichiometric conditions [1]. Yet oxygen-rich exhausts make the Three-Way Catalysts, usually containing bimetallic Pt–Rh or Pd–Rh systems, developed in the early 1980s ineffective in the reduction of the nitrogen oxides (NO and NO<sub>2</sub>: NO<sub>x</sub>) produced by lean burn engines [1].

Miyadera first reported on the promising potential of the Ag/Al<sub>2</sub>O<sub>3</sub> system for the Selective Catalytic Reduction of NO<sub>x</sub> by various hydrocarbons (HC-SCR) [2], due to its elevated selectivity in N<sub>2</sub> compared to the platinum group metals-supported catalysts as reported by Burch [1]. Moreover, Miyadera revealed the existence of an optimum loading of silver (2 wt%) on alumina in the C<sub>3</sub>H<sub>6</sub>-SCR reaction [2]. To date, the existence of such an optimum loading of Ag has been confirmed by several groups [3–8] for Ag/Al<sub>2</sub>O<sub>3</sub> samples

prepared via the commonly used impregnation technique. Other groups reported that Ag(2 wt%)/Al<sub>2</sub>O<sub>3</sub> catalysts exhibited higher C<sub>3</sub>H<sub>6</sub>-SCR performances than Ag/Al<sub>2</sub>O<sub>3</sub> samples containing much higher Ag loadings [9–11]. In contrast, few studies concluded to an optimum Ag loading either much lower [12] or much higher [13] than 2 wt%.

The reason for the existence of an optimum Ag loading for Ag/Al<sub>2</sub>O<sub>3</sub> catalysts in the C<sub>3</sub>H<sub>6</sub>-SCR of NO<sub>x</sub> has not been clearly understood to date. Studies have almost exclusively focused on the characterization of the Ag phases [3–11,13]. The characterization of the Ag phases is not trivial and it has been shown that various silver species are present on the Ag/Al<sub>2</sub>O<sub>3</sub> materials [14 and references therein], such as Ag<sub>2</sub>O clusters or Ag<sup>+</sup> ions, electron-deficient Ag clusters (Ag<sub>n</sub><sup>δ+</sup>), although the presence of Ag<sub>n</sub><sup>δ+</sup> species under the HC-SCR reaction is still being debated [15], and metallic Ag<sup>0</sup> nanoparticles and clusters. Several groups have concluded that Ag is predominantly present as Ag<sub>2</sub>O clusters over all range of Ag loadings [9,16]. For the highest Ag loadings, however, larger Ag<sub>2</sub>O clusters can be reduced to Ag<sup>0</sup> nanoparticles in the course of the HC-SCR reaction [4,9,17]. This would account for the observed decrease in the C<sub>3</sub>H<sub>6</sub>-SCR performances of highly-loaded Ag/Al<sub>2</sub>O<sub>3</sub> catalysts due to the preferential oxidation of the hydrocarbon reductant on the Ag<sup>0</sup> nanoparticles, at the expense of its use for the reduction of NO<sub>x</sub> on the oxidized Ag species [2,9,17].

To date, the work reported by Wang et al. [18] is the only study in which the influence of the Ag loading was investigated from “the point of view of changes in the surface properties of the Al<sub>2</sub>O<sub>3</sub>

support". Recently, we proposed that the surfaces of oxides, which is typically the case of the Ag/Al<sub>2</sub>O<sub>3</sub> system, could be characterized by the adsorption of NO<sub>x</sub> followed by their temperature-programmed desorption (NO<sub>x</sub>-TPD [19,20]) and we reported that the introduction of Ag on Al<sub>2</sub>O<sub>3</sub> led to a decrease in the amount of NO<sub>x</sub> stored on Al<sub>2</sub>O<sub>3</sub> [21], suggesting that the NO<sub>x</sub> species would only be chemisorbed on the Al<sub>2</sub>O<sub>3</sub> sites free of Ag. The aim of the present work is to gain further understanding on the origin of the existence of an optimum Ag loading in the Ag/Al<sub>2</sub>O<sub>3</sub> samples prepared by impregnation for the C<sub>3</sub>H<sub>6</sub>-SCR of NO<sub>x</sub> via the characterization of the available Al<sub>2</sub>O<sub>3</sub> surface in Ag/Al<sub>2</sub>O<sub>3</sub> catalysts by NO<sub>x</sub>-TPD.

## 2. Experimental

### 2.1. Catalyst synthesis and characterization

The γ-Al<sub>2</sub>O<sub>3</sub> support (Procatalyse, 180 m<sup>2</sup>/g) was ground and sieved, and the fraction between 0.200 and 0.315 mm was used to prepare the Ag-promoted samples. The introduction of Ag was performed by incipient wetness impregnation of the bare Al<sub>2</sub>O<sub>3</sub> support (0.7 cm<sup>3</sup>/g porous volume) by aqueous solutions of AgNO<sub>3</sub> (Aldrich, >99%) to achieve silver loadings varying from 0.5 to 4.3 wt%, which were ascertained by inductively coupled plasma atomic emission spectroscopy (ICP-AES, CNRS – Solaize). After impregnation, the Ag-loaded samples were aged for 4 h under ambient conditions and subsequently dried at 100 °C overnight. Finally, the Ag-loaded samples were calcined at 600 °C (3 °C/min) for 4 h in a muffle furnace. From here on, the samples will be denoted as Ag(x)/Al<sub>2</sub>O<sub>3</sub>, where x represents the Ag surface density expressed as the number of Ag atoms per nm<sup>2</sup> of support (Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub>), in which the BET surface of the sample was corrected for the content of Ag as Ag<sub>2</sub>O, although this correction is less critical than that which must be done for tungstated zirconias with high W loadings [20].

N<sub>2</sub>-sorption measurements were carried out on a Belsorp max instrument (Bel Japan) at 77 K after evacuation of the samples at 300 °C for 3 h.

### 2.2. C<sub>3</sub>H<sub>6</sub>-SCR runs

The steady state catalytic experiments were carried out in a U-type quartz reactor (12 mm i.d.). It is important to note that in contrast with most of the studies published to date, the amount of silver introduced in the catalyst bed was maintained constant. The samples were held on plugs of quartz wool and consisted in 0.38 g of mechanical mixtures of Ag(x)/Al<sub>2</sub>O<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub> of the same grain sizes in which the amount of Ag was equal to 30.9 ± 1.2 μmol. The temperature of the tubular furnace was set by a Eurotherm 2408 temperature controller using a K type thermocouple. Prior to the C<sub>3</sub>H<sub>6</sub>-SCR experiments, the samples were calcined in situ in O<sub>2</sub>(20%)-He at 550 °C (3 °C/min) for 2 h with a flow rate of 100 mL<sub>NTP</sub>/min. After cooling down to 150 °C, the samples were exposed to the C<sub>3</sub>H<sub>6</sub>-SCR reaction mixture. NO (4000 ppm/He), C<sub>3</sub>H<sub>6</sub> (2000 ppm/He), O<sub>2</sub> (100%) and He (100%) were fed from independent mass flow controllers (Brooks 5850TR). Typically, the composition of the C<sub>3</sub>H<sub>6</sub>-NO-O<sub>2</sub>-He reaction mixture was: 400 ppm C<sub>3</sub>H<sub>6</sub>, 385 ppm NO<sub>x</sub> (~96% NO) and 8% O<sub>2</sub> in He, and the total flow rate was 230 mL<sub>NTP</sub>/min. The temperature was increased stepwise from 150 to 550 °C with 25 °C increments and left for about 1 h at each temperature step. The reactor outflow was analyzed using a μ-GC (Varian, CP4900) equipped with two channels. The first channel, a 5A molecular sieve column (80 °C, 150 kPa He, 200 ms injection time, 30 s backflush time), was used to separate N<sub>2</sub>, O<sub>2</sub> and CO. The second channel, equipped with a poraplot Q

**Table 1**

Compositions, surface areas and Ag densities of the studied samples.

Catalysts	Ag (wt%)	Surface area		Ag surface density	
		m <sup>2</sup> /g	m <sup>2</sup> /g <sub>Al<sub>2</sub>O<sub>3</sub></sub>	Ag/nm <sup>2</sup> <sub>Al<sub>2</sub>O<sub>3</sub></sub> **	mg Ag/m <sup>2</sup>

\*\* Ag surface density corrected for the content of Ag as Ag<sub>2</sub>O following the procedure described in ref. [20].

column (60 °C, 150 kPa He, 200 ms injection time), was used to separate CO<sub>2</sub>, N<sub>2</sub>O, C<sub>3</sub>H<sub>6</sub> and H<sub>2</sub>O. A chemiluminescence NO<sub>x</sub> analyzer (Thermo Environmental Instruments 42C-HT) allowed the simultaneous detection of both NO and NO<sub>2</sub>. NO<sub>x</sub> conversions to N<sub>2</sub> were calculated as follows:

$$X \text{ NO}_x \text{ to N}_2(\%) = \frac{2 \times [\text{N}_2]}{[\text{NO}_x]_{\text{inlet}} \times 100} \quad (1)$$

where [NO<sub>x</sub>]<sub>inlet</sub> and [N<sub>2</sub>] were the concentrations in NO<sub>x</sub> and N<sub>2</sub> measured at the inlet and the outlet of the reactor, respectively. Minute amounts of N<sub>2</sub>O, below 5 ppm, were also detected. C<sub>3</sub>H<sub>6</sub> conversions were calculated on the basis of the CO<sub>x</sub> (CO + CO<sub>2</sub>) products formed:

$$X \text{ C}_3\text{H}_6(\%) = \frac{[\text{CO}] + [\text{CO}_2]}{[\text{C}_3\text{H}_6]_{\text{inlet}} \times 3} \times 100 \quad (2)$$

where [CO], [CO<sub>2</sub>] and [C<sub>3</sub>H<sub>6</sub>]<sub>inlet</sub> were the concentrations of CO and CO<sub>2</sub> measured at the outlet of the reactor and that of C<sub>3</sub>H<sub>6</sub> measured at the inlet of the reactor, respectively.

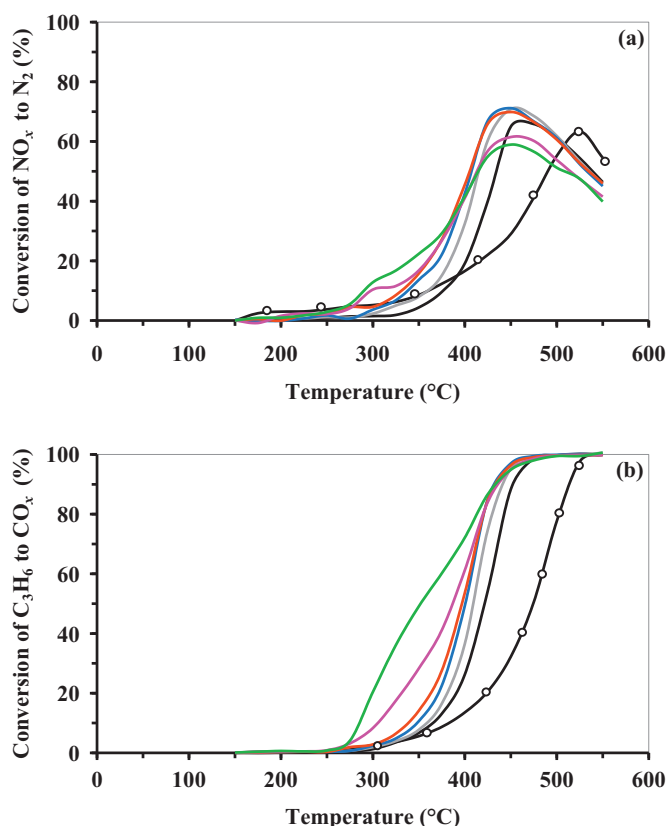

### 2.3. NO<sub>x</sub>-TPD experiments

Prior to the NO<sub>x</sub>-TPD experiments, the samples were calcined in situ in O<sub>2</sub>(20%)-He at 500 °C (3 °C/min) for 2 h with a flow rate of 100 mL<sub>NTP</sub>/min. The samples (about 0.2 g of Ag(x)/Al<sub>2</sub>O<sub>3</sub>) were firstly contacted with a NO-O<sub>2</sub>-He (385 ppm-8% - balance, 230 mL<sub>NTP</sub>/min) mixture at room temperature (RT) until recovery of the inlet NO<sub>x</sub> concentration. The samples were then flushed with O<sub>2</sub>(8%)-He at RT to remove weakly chemisorbed NO<sub>x</sub> species until the disappearance of the NO<sub>x</sub> species in the O<sub>2</sub>-He stream. The NO<sub>x</sub>-TPD experiments were carried out from RT to 600 °C, at a heating rate of 3 °C/min. The reactor outflow was continuously monitored using the abovementioned chemiluminescence NO<sub>x</sub> detector.

## 3. Results and discussion

Table 1 shows that the contents of Ag varied from 0 to 4.3 wt% in the Ag(x)/Al<sub>2</sub>O<sub>3</sub> catalysts. The BET surface area of these samples was found to be close to that of the bare Al<sub>2</sub>O<sub>3</sub> support and the surface area calculated per g of Al<sub>2</sub>O<sub>3</sub>, when corrected for the content of Ag as Ag<sub>2</sub>O, remained essentially constant (180 ± 3 m<sup>2</sup>/g<sub>Al<sub>2</sub>O<sub>3</sub></sub>). The Ag surface densities were found to vary from 0.0 to 1.3 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub>.

The catalytic performances of the Ag(x)/Al<sub>2</sub>O<sub>3</sub> samples in the C<sub>3</sub>H<sub>6</sub>-SCR of NO<sub>x</sub> are shown in Fig. 1. As expected from earlier studies [2–8], the Ag(0.6)/Al<sub>2</sub>O<sub>3</sub> and Ag(0.7)/Al<sub>2</sub>O<sub>3</sub> catalysts, with Ag loadings close to 2 wt% (Table 1), showed optimum conversions of NO<sub>x</sub> to N<sub>2</sub> (Fig. 1a). Ag(0.4)/Al<sub>2</sub>O<sub>3</sub> also exhibited conversion as high as that of the aforementioned samples but at slightly

**Fig. 1.** (a) NO<sub>x</sub> conversion to N<sub>2</sub> and (b) C<sub>3</sub>H<sub>6</sub> conversion to CO<sub>x</sub> vs. reaction temperature for Al<sub>2</sub>O<sub>3</sub> (—○—), Ag(0.3)/Al<sub>2</sub>O<sub>3</sub> (black), Ag(0.4)/Al<sub>2</sub>O<sub>3</sub> (grey), Ag(0.6)/Al<sub>2</sub>O<sub>3</sub> (blue), Ag(0.7)/Al<sub>2</sub>O<sub>3</sub> (red), Ag(0.8)/Al<sub>2</sub>O<sub>3</sub> (purple) and Ag(1.1)/Al<sub>2</sub>O<sub>3</sub> (green). (For interpretation of the references to color in figure legend, the reader is referred to the web version of the article.)

higher temperatures, whereas the performances of Ag(0.3)/Al<sub>2</sub>O<sub>3</sub> were clearly lower than those of the previous samples. This was also the case for the highly-loaded catalysts (Ag(0.8)/Al<sub>2</sub>O<sub>3</sub> and Ag(1.1)/Al<sub>2</sub>O<sub>3</sub>) although it can also be seen that these samples showed slightly higher conversions of NO<sub>x</sub> to N<sub>2</sub> than Ag(0.6)/Al<sub>2</sub>O<sub>3</sub> and Ag(0.7)/Al<sub>2</sub>O<sub>3</sub> below 375 °C (Fig. 1a). This particular behavior can be attributed to the better efficiency of the Ag(0.8)/Al<sub>2</sub>O<sub>3</sub> and Ag(1.1)/Al<sub>2</sub>O<sub>3</sub> catalysts to convert C<sub>3</sub>H<sub>6</sub> at the lower temperatures (Fig. 1b), which results in a broadening of the NO<sub>x</sub> reduction temperature window in line with earlier results [2]. Yet the higher activity of these two catalysts in propene oxidation also leads to a decrease in the NO<sub>x</sub> conversion at high temperatures, the combustion of C<sub>3</sub>H<sub>6</sub> occurring at the expense of its reaction with NO to produce N<sub>2</sub> [2]. The reason for the increased rate of C<sub>3</sub>H<sub>6</sub> oxidation on the highly-loaded catalysts has been attributed to a decrease in the dispersion of Ag resulting from the formation of large Ag<sub>2</sub>O clusters which could be reduced to Ag<sup>0</sup> particles by the hydrocarbons, the metallic Ag<sup>0</sup> particles being very active for the undesired complete oxidation of propene [4,9,17]. Fig. 2 summarizes the NO<sub>x</sub> conversions to N<sub>2</sub> as a function of the Ag surface density at temperatures of 400, 425 and 450 °C. As mentioned above, a decrease in NO<sub>x</sub> conversion is observed for Ag surface densities greater than 0.7 Ag/nm<sup>2</sup> Al<sub>2</sub>O<sub>3</sub> at any temperature, hence for Ag loadings higher than 2.2 wt% (Table 1). Overall, below 0.7 Ag/nm<sup>2</sup> Al<sub>2</sub>O<sub>3</sub>, an increase in the C<sub>3</sub>H<sub>6</sub>-SCR performances is observed with an increase in Ag surface density, although the amount of Ag in the Ag(x)/Al<sub>2</sub>O<sub>3</sub>-Al<sub>2</sub>O<sub>3</sub> mechanical mixture was kept constant (Section 2.2). It can also be noted from Fig. 2 that the range of Ag surface

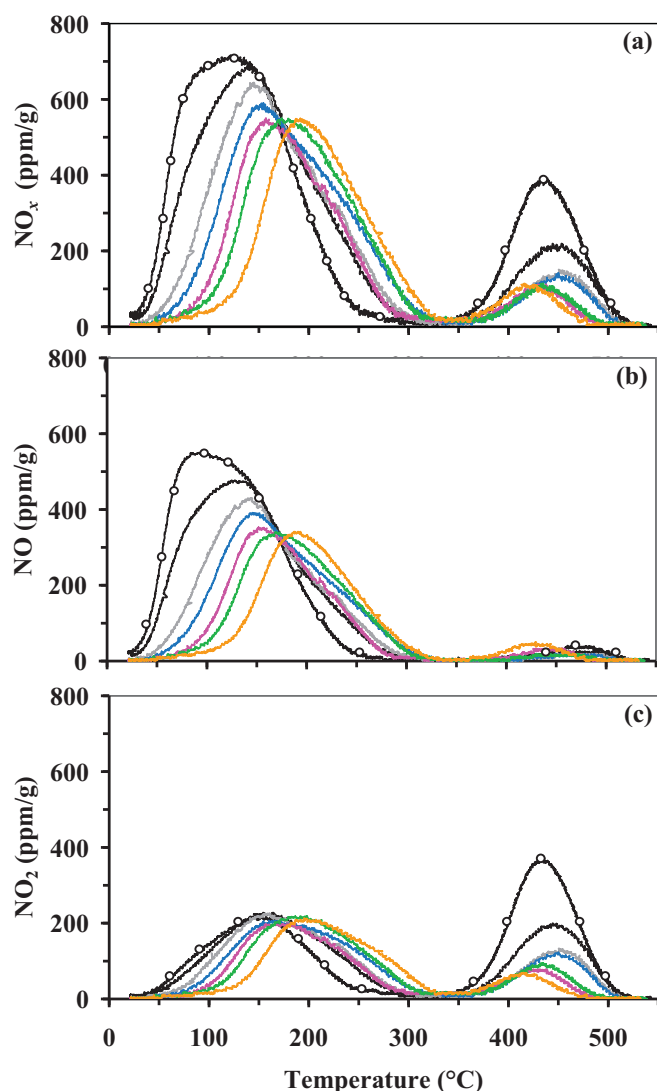

**Fig. 2.** NO<sub>x</sub> conversion to N<sub>2</sub> at various reaction temperatures as a function of the Ag surface density.

densities with optimum conversion of NO<sub>x</sub> to N<sub>2</sub> broadens as the temperature increases, in agreement with earlier investigations [2].

For the sake of clarity, only the NO<sub>x</sub>-TPD profiles of some of the Ag(x)/Al<sub>2</sub>O<sub>3</sub> samples are shown in Fig. 3. These NO<sub>x</sub>-TPD profiles exhibit low temperature (LT < 350 °C) and high temperature (HT > 350 °C) desorption peaks, in line with earlier investigations [21]. Such desorption profiles are consistent with those reported by Guo and co-workers obtained after exposure of Ag/Al<sub>2</sub>O<sub>3</sub> samples to NO–O<sub>2</sub>–He (1000 ppm – 8% – balance) at RT [22,23], thus under experimental conditions close to those reported in the present work. Fig. 3a shows that the addition of increasing contents of Ag leads to a decrease in the intensity of both peaks up to an Ag surface density of about 0.8 Ag/nm<sup>2</sup> Al<sub>2</sub>O<sub>3</sub>, which suggests that the NO<sub>x</sub> species do not chemisorb on the Ag species, presumably Ag<sub>2</sub>O clusters for freshly calcined samples [9,15,16]. A similar conclusion has been drawn by Sazama et al. [24] on the basis of FTIR measurements carried out on Al<sub>2</sub>O<sub>3</sub> and an Ag/Al<sub>2</sub>O<sub>3</sub> sample (1.76 wt% Ag), albeit at somewhat higher temperatures (~200 °C). In agreement with the conclusions of Sazama et al. [24], this indicates that Ag has blocked part of the Al<sub>2</sub>O<sub>3</sub> sites available for NO<sub>x</sub> chemisorption. For Ag surface densities higher than 0.8 Ag/nm<sup>2</sup> Al<sub>2</sub>O<sub>3</sub> the intensity of the NO<sub>x</sub>-TPD profiles remains essentially constant (Fig. 3a). The temperature at maximum NO<sub>x</sub> desorption of the HT peak shifts slightly to lower temperatures (ΔT ~ 20 °C) with increasing Ag surface density, whereas the temperature at maximum NO<sub>x</sub> desorption of the LT peak shifts to higher temperatures (ΔT ~ 70 °C) (Fig. 3a). The shift of the NO<sub>x</sub> HT peak to slightly lower temperatures can be reasonably attributed to a decrease in the amounts of NO<sub>x</sub> released. Such an explanation can not be accounted for the shift of the NO<sub>x</sub> LT peak to higher temperatures, as in this particular case the amounts of NO<sub>x</sub> released remain essentially constant for Ag surface densities greater than or equal to 0.8 Ag/nm<sup>2</sup> Al<sub>2</sub>O<sub>3</sub> (Fig. 3). This shift of the NO<sub>x</sub> LT peak to higher temperatures may be attributed to a strengthening in the bonding of the NO<sub>x</sub> ad-species with increasing Ag loadings due to an increase in the basicity of Al<sub>2</sub>O<sub>3</sub> with the introduction of increasing amounts of Ag [18].

In the case of tungstated zirconias, for which it was found that the NO<sub>x</sub> species did not chemisorb on tungstates, we showed that the accessible surface of ZrO<sub>2</sub> was correlated with the NO<sub>x</sub> uptake of the studied samples [19,20]. The NO<sub>x</sub> uptakes of the Ag(x)/Al<sub>2</sub>O<sub>3</sub> samples are summarized in Fig. 4. As in the case of the tungstated zirconias [19,20], the NO<sub>x</sub> uptake decreases linearly with a rather good correlation coefficient ( $R^2 = 0.94$ ) and then levels off. Taking into account the maximum deviation of the NO<sub>x</sub> uptakes from the linear plot up to 0.8 Ag/nm<sup>2</sup> Al<sub>2</sub>O<sub>3</sub>, it can be concluded that the leveling off of the NO<sub>x</sub> uptakes occurs at Ag surface densities greater than or equal to 0.7 Ag/nm<sup>2</sup> Al<sub>2</sub>O<sub>3</sub>, hence for silver loadings close to

**Fig. 3.** (a)  $\text{NO}_x$ -, (b)  $\text{NO}$ - and (c)  $\text{NO}_2$ -TPD profiles of  $\text{Al}_2\text{O}_3$  (—○—),  $\text{Ag}(0.3)/\text{Al}_2\text{O}_3$  (black),  $\text{Ag}(0.4)/\text{Al}_2\text{O}_3$  (grey),  $\text{Ag}(0.6)/\text{Al}_2\text{O}_3$  (blue),  $\text{Ag}(0.8)/\text{Al}_2\text{O}_3$  (purple),  $\text{Ag}(1.1)/\text{Al}_2\text{O}_3$  (green) and  $\text{Ag}(1.3)/\text{Al}_2\text{O}_3$  (orange). (For interpretation of the references to color in figure legend, the reader is referred to the web version of the article.)

2 wt% (Fig. 4). This suggests that pseudo monolayer coverage of  $\text{Al}_2\text{O}_3$  by the  $\text{Ag}_2\text{O}$  clusters has been reached at such a Ag surface density/Ag loading. In other words, the  $\text{Al}_2\text{O}_3$  surface sites onto which Ag is anchored are saturated for Ag surface densities greater than or equal to  $0.7 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$  corresponding to Ag loadings close to 2 wt% (Fig. 4). At higher Ag surface densities/Ag loadings, this implies that the dispersion of Ag decreases. The slope of the line obtained in Fig. 4 ( $-1.36 \mu\text{mol NO}_x \text{ m}^{-2}/\text{Ag nm}^{-2}_{\text{Al}_2\text{O}_3} = -0.8 \text{ NO}_x \text{ molec.}/\text{Ag atom}$ ), which indicates that 1 Ag atom prevents the adsorption of 0.8 molecule of  $\text{NO}_x$ , provides additional support for the existence of Ag in a highly dispersed state up to pseudo monolayer coverage, i.e.  $0.7 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$  (2.2 wt% Ag). Breen et al. also concluded to the  $0.7 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$  of Ag in a freshly calcined  $\text{Ag}(2 \text{ wt\%})/\text{Al}_2\text{O}_3$  sample by estimating an average Ag–Ag coordination number lower than unity by EXAFS [15].

It is remarkable that the Ag surface density for which maximum dispersion of Ag is achieved on  $\text{Al}_2\text{O}_3$  ( $0.7 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$ ), as determined by the  $\text{NO}_x$ -TPD method (Fig. 4), also corresponds to the optimum composition for which maximum  $\text{C}_3\text{H}_6$ -SCR

**Fig. 4.**  $\text{NO}_x$  uptakes as a function of the Ag surface density.

performances are observed in the present work (Figs. 1 and 2). Our catalytic results (Fig. 2) are also consistent with those reported previously in the literature for which a drop in the HC-SCR performances was observed for Ag surface densities greater than  $0.7 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$  [2,4,5,8]. The use of this Ag surface density concept allows rationalizing some of the earlier results. As a first example, it can be found that the optimum Ag loading of  $\text{Ag}-\text{Al}_2\text{O}_3$  catalysts in the  $\text{C}_3\text{H}_6$ -SCR reaction was 1.0 wt% in the studies reported by Meunier et al. [12]. In this work, however, the specific surface area of the bare  $\text{Al}_2\text{O}_3$  support was lower ( $115 \text{ m}^2/\text{g}$ , [12]) than those usually reported in comparable studies ( $152\text{--}260 \text{ m}^2/\text{g}$ ) [2,4,5,8]. Interestingly, Meunier et al. reported on an optimum composition of the  $\text{Ag}/\text{Al}_2\text{O}_3$  catalysts in terms of Ag surface density, as they referred to an optimum silver loading of  $0.087 \text{ mg}/\text{m}^2_{\text{Al}_2\text{O}_3}$  [12]. This optimum value, to which corresponds an Ag surface density of about  $0.5 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$ , is thus rather close to that reported in the present work and those that can be deduced from earlier studies [2,4,5,8]. In agreement with the results of the present study, Meunier et al. also found that the performances in the  $\text{C}_3\text{H}_6$ -SCR reaction of the  $\text{Ag}/\text{Al}_2\text{O}_3$  catalysts decreased to a significant extent for Ag surface densities greater than or equal to  $0.7 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$  (Ag loadings  $\geq 1.5 \text{ wt\%}$ ) [12]. As a second example, Jen [25] concluded that average pore size and pore-size distribution could be important factors for the catalytic performances of  $\text{Ag}(2 \text{ wt\%})/\text{Al}_2\text{O}_3$ -i catalysts prepared with various starting  $\text{Al}_2\text{O}_3$  supports (i). The author observed that the most active Ag samples (supported on  $\text{Al}_2\text{O}_3$ -1 and  $\text{Al}_2\text{O}_3$ -2 carriers) in the  $\text{C}_3\text{H}_6$ -SCR reaction were those exhibiting “the largest fractions of pores in the  $15\text{--}100 \text{ \AA}$  range as well as the largest fractions in the most populated  $50 \text{ \AA}$  range”. Although there is no mention of the temperature at which the  $\text{NO}_x$  conversions were measured [25], the catalytic  $\text{C}_3\text{H}_6$ -SCR performances reported by Jen may also be rationalized in terms of Ag surface density of the studied  $\text{Ag}(2 \text{ wt\%})/\text{Al}_2\text{O}_3$ -i samples. Indeed, we could calculate that their two most active catalysts,  $\text{Ag}/\text{Al}_2\text{O}_3$ -1 and  $\text{Ag}/\text{Al}_2\text{O}_3$ -2, displayed Ag surface densities of  $0.5$  and  $0.6 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$ , respectively, whereas the least active samples,  $\text{Ag}/\text{Al}_2\text{O}_3$ -3 and  $\text{Ag}/\text{Al}_2\text{O}_3$ -5, exhibited Ag surface densities of  $0.4$  and  $1.2 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$ , respectively. Considering the Ag surface density concept developed in the present study, the most active catalysts evaluated by Jen [25] displayed Ag surface densities ( $0.5$  and  $0.6 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$ ) similar to the optimum value ( $0.7 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$ ), as a plateau in the  $\text{C}_3\text{H}_6$ -SCR reaction dependence with the Ag surface density may exist depending on the temperature at which the catalytic performances are considered (Fig. 2). The lower  $\text{C}_3\text{H}_6$ -SCR performances of  $\text{Ag}/\text{Al}_2\text{O}_3$ -5 is explained by the fact that this sample exhibited a much higher Ag surface density ( $1.2 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$ ) than those of the optimum catalysts ( $0.6\text{--}0.7 \text{ Ag}/\text{nm}^2_{\text{Al}_2\text{O}_3}$ , Figs. 2 and 4),

whereas those of Ag/Al<sub>2</sub>O<sub>3</sub>-3 can be related to its lower Ag surface density (0.4 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub>), as also observed in our work (Fig. 2). Our concept does not apply, however, to the work of He et al. [13]. In this particular study, it was found that Ag/Al<sub>2</sub>O<sub>3</sub> catalysts with much higher silver loadings than 2 wt% (4–8 wt%), – for Al<sub>2</sub>O<sub>3</sub> supports of 210–240 m<sup>2</sup>/g [13] and thus for Ag surface densities greater than 0.7 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub> and as high as 2.0 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub> – were much more active in the C<sub>3</sub>H<sub>6</sub>-SCR reaction than Ag(2 wt%)/Al<sub>2</sub>O<sub>3</sub>. To our knowledge, this study is the only one in which such a behavior has been reported. One can also note that the catalytic performances of the Ag(2 wt%)/Al<sub>2</sub>O<sub>3</sub> reported by He et al. in the C<sub>3</sub>H<sub>6</sub>-SCR reaction [13] were found to be particularly low in the 200–500 °C range of temperatures.

Finally, the importance of the concept of Ag surface density has also been highlighted recently by Orlyk and co-workers in the C<sub>2</sub>H<sub>5</sub>OH-SCR of NO<sub>x</sub> [26]. In their study, optimum catalytic performances were reported for surface concentrations of Ag of 0.09–0.13 mg/m<sup>2</sup>. These values compare well with those reported by Meunier et al. (0.087 mg/m<sup>2</sup> [12]) and in the present work (0.07–0.12 mg/m<sup>2</sup>, Table 1 and Fig. 1) in the case of the C<sub>3</sub>H<sub>6</sub>-SCR of NO<sub>x</sub>.

#### 4. Conclusion

Ag/Al<sub>2</sub>O<sub>3</sub> catalysts with various Ag loadings were synthesized by the common impregnation technique and characterized by the NO<sub>x</sub>-TPD method. It was found that the NO<sub>x</sub> uptake decreased linearly with the Ag surface density up to about 0.7 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub> and then leveled off. This was attributed to the fact that the maximum dispersion of Ag<sub>2</sub>O clusters is achieved at an optimum Ag surface density of about 0.7 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub>, corresponding to an optimum Ag loading of about 2 wt%. It was also found that this optimum Ag surface density could be correlated to the catalytic performances in the C<sub>3</sub>H<sub>6</sub>-SCR of NO<sub>x</sub> in terms of conversion of NO<sub>x</sub> to N<sub>2</sub>. For Ag surface densities higher than 0.7 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub>, a decrease in the C<sub>3</sub>H<sub>6</sub>-SCR catalytic performances was observed, whereas at lower Ag surface densities the C<sub>3</sub>H<sub>6</sub>-SCR catalytic performances increased with increasing Ag surface densities. This work thus provides convincing arguments that the origin of the optimum Ag loading on Al<sub>2</sub>O<sub>3</sub>, reported to be about 2 wt% in the literature and deduced to be about 0.7 Ag/nm<sup>2</sup><sub>Al<sub>2</sub>O<sub>3</sub></sub> according to the present study, results from the maximum loading of silver per unit surface area of Al<sub>2</sub>O<sub>3</sub> for which Ag<sub>2</sub>O clusters remain highly dispersed on freshly

calcined samples. The use of the Ag surface density concept allowed rationalizing some of the earlier results on C<sub>3</sub>H<sub>6</sub>-SCR of NO<sub>x</sub>.
